Coupling an Earth system model to a multisector dynamics model

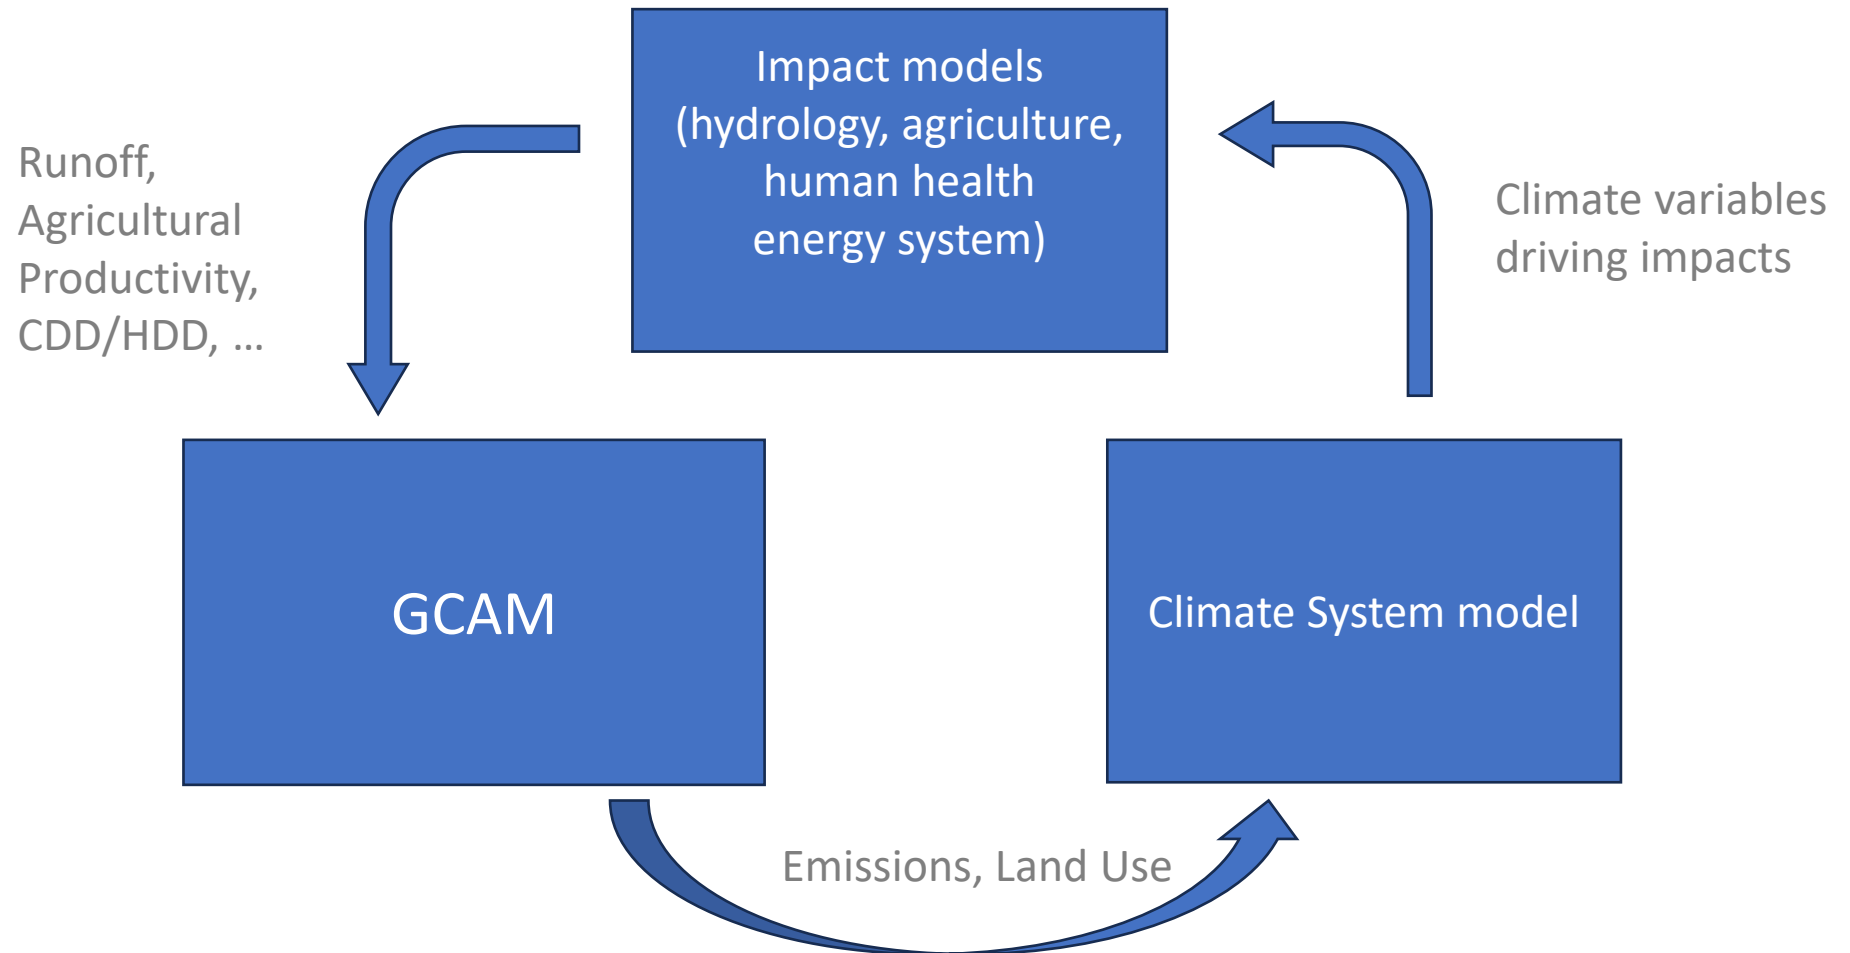

We take the perspective of GCAM modelers

And we are concerned with this component

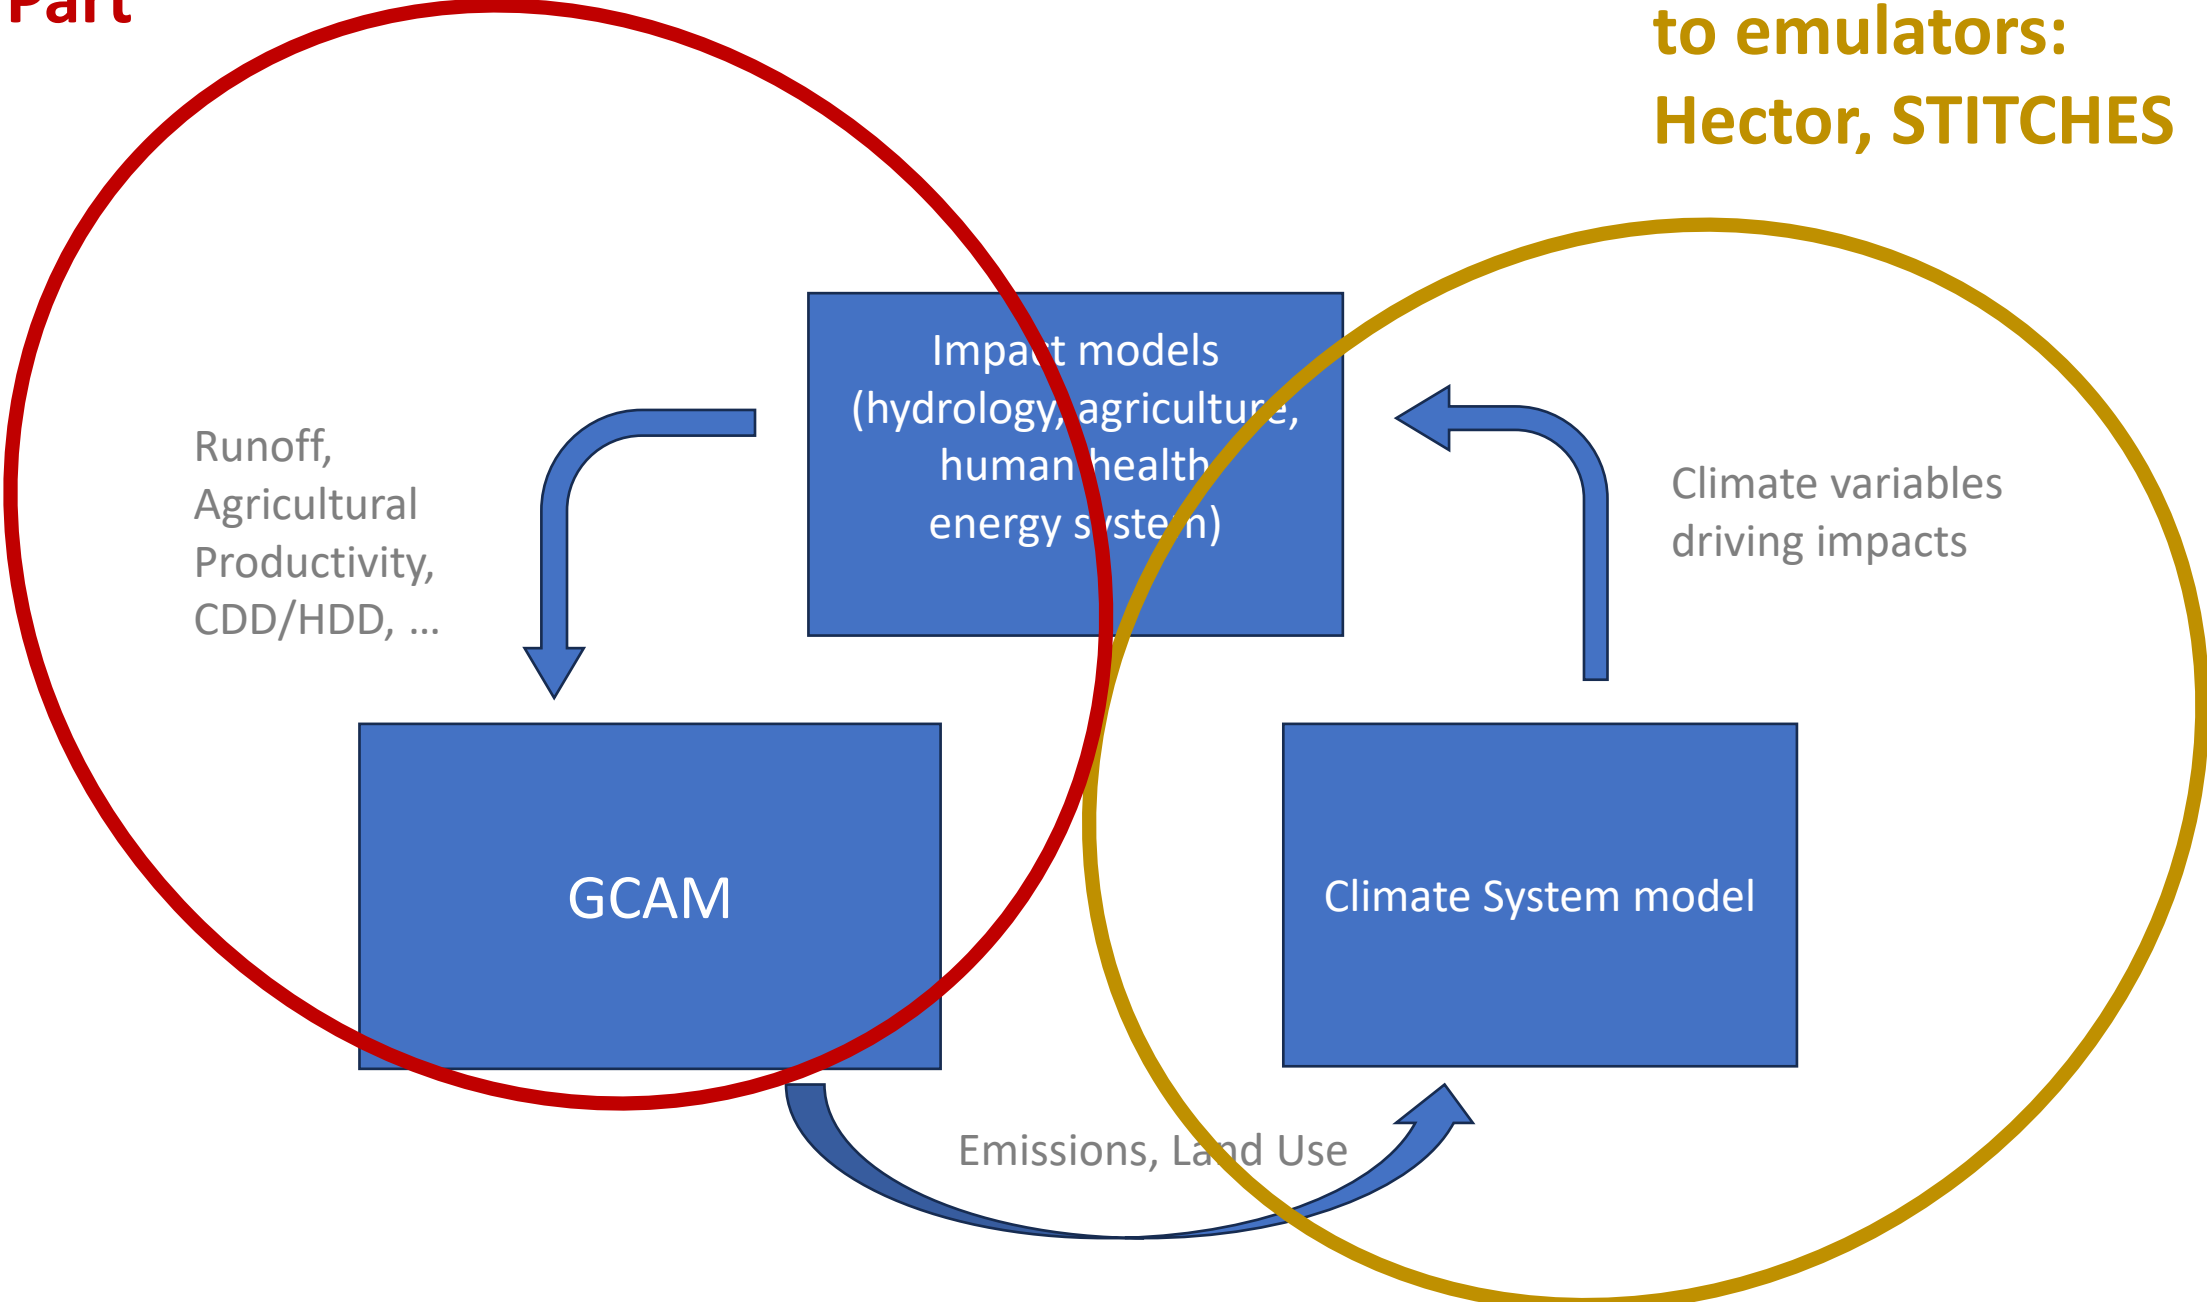

How to best represent the **Earth system** in a model like GCAM?

Note that some of these thoughts should be also relevant to the ESM modelers thinking about hardwiring GCAM to E3SM

Hard Part

**Easy part thanks
to emulators:
Hector, STITCHES**

The hard part (Challenges)

Which impacts should we model?

At which scale (GCAM works by regions, impacts happen at local scales)?

At which frequency? (how do high frequency impacts manifest themselves in a 5-year time step (current GCAM frequency)? In a 1-year time step?)

What type of impact models?

- Process-based?

- Empirical?

- Damage functions?

How do we account for uncertainties?

Opportunities

We have started from a set of impacts for which previous modeling work provided a template for implementation.

We plan to **continue adding impacts:**

- Labor productivity (ongoing)
- Wildfires
- More impacts linked to extremes (damages from natural disasters)
- Sea level rise...
- Non-climate impacts are impacts too! E.g., air pollution.

We plan to **shorten the time step of GCAM (from 5 year to 1 year)** to better represent short term disturbances (extremes)

We also plan to revisit all this with the macro implementation (**GDP becomes endogenous**)
Based on our initial scenarios, **endogenous GDP, which itself is indirectly affected by physical impacts, will be potentially affected at a scale that may produce global effects.**

Coordinated activities

Use a **hierarchy of models**, from emulators to process models, to model hazards and impacts and represent them into GCAM at the right spatial and temporal scale.

The same applies to representing impacts within E3SM and GCAM coupled system.

- Damages from extremes;

- sea level rise

- climate induced migration

- impacts of climate on land-based mitigation solutions (afforestation, CDR, ocean carbon sinks)

From scenarios to storylines and back: how do we represent uncertainties when the modeling system becomes more and more complex? Can we use storylines instead of full-blown exploratory modeling? Can we connect the former to the latter?

Thank you

Hard Coupling (hard-wiring model within model) or Soft Coupling (give inputs/take outputs to/from a model run offline) ?

- When **feedbacks leave a footprint at the global scale**, altering the trajectory of a scenario from its reference case (without climate impacts), full integration, **hard coupling**, should be implemented.
- When **feedbacks are not as large** to influence the trajectory of global temperature/GHG emissions **soft coupling** should suffice. In this case, we are still interested in **regional and distributional impacts**, changes in trade patterns, food availability, food prices, food security, other measures of well being that only an integrated model can represent, but that integration does not need to be step by step.
